

Beacon geometry is method-specific

Median error over all 100 fixes

Failed = raised, refused, stalled, or landed >100 m away

Hatched bars are medians made mostly of failed fixes: on the collinear array the beacon centroid lies on the line of symmetry, so TOA and TDOA never leave it, and their 6.77 m is the distance from the seed to the truth. AOA is the best of the three there.

TDOA's height is a dataset defect, not geometry: `tdoa_diffs.txt` stores $d_{ref} - d_k$ where the solver predicts $d_k - d_{ref}$.

Correct the sign and the square array gives 0.074 m, the 0.087 m its GDOP predicts. See `test_tdoa_dataset_sign_convention.py`.
